## 1 Problem Statement

By listing the first six prime numbers: 2, 3, 5, 7, 11, and 13, we can see that the 6th prime is 13.

What is the  $N$ -th prime number?

## 2 My Algorithm

We use the following identity, which is a consequence of the Prime Number Theorem:

$$n(\log n + \log \log n - 1) < p_n < n(\log n + \log \log n), n > 5. \quad (1)$$

If  $n \leq 5$ , we use a look-up table. Using a Sieve of Eratosthenes, we generate a list of the primes up to  $n(\log n + \log \log n)$ , which is guaranteed to contain the  $n$ -th prime. Our answer is the  $n$ -th element of this array. We do this with time complexity  $O(n \log n \log \log(n \log n))$ , using  $p_n \approx n \log n$ . Because  $O(\log \log(n \log n)) \in O(\log n)$ , this can be simplified to  $O(n \log^2 n)$ .

To optimize the constant factor, we compute the first  $N_{\max} = 10^4$  primes and store them in memory, rather than computing the list for each query, which takes too long.
